**Abstract**—X-ray diffraction and chemical analyses were performed on clay fractions separated from an acid brown soil (Dystrochrept) by means of size fractionations using high-gradient magnetic separation techniques. Breakdown of large phyllosilicates preexisting in the saprolite involved physical fragmentation and mineralogical transformations strongly related to chemical weathering.

Compared to the C horizon, the proportion of chlorite and vermiculite decreased strongly in the silt and coarse-clay fractions of the A1 horizon, but was maintained in the finer clay fraction ( $<1\ \mu\text{m}$ ). The distribution of mica in the different fractions was quite the opposite. Micas are the major component of the A1, 1–2  $\mu\text{m}$  fractions, and their proportion progressively decreased with decreasing fraction size. Thus, it is concluded that during fragmentation and/or simple transformation of the larger phyllosilicates, clusters of chlorite, mica/vermiculite, and vermiculite layers were preferentially affected. A concentration of mica layers took place in the coarse clay fractions as chlorite and vermiculite residues were accumulated in the fine clays.

The process involved the loss of Fe and Mg, leaving, or forming, more aluminous dioctahedral minerals. As the transformation processes occurred, dissolution of preexisting minerals led to the precipitation of amorphous and/or crystalline Fe- and Al-oxides, and possibly of phyllosilicates. The new phyllosilicates appear to be montmorillonitic.

The most abundant end products of the weathering processes in either the A1 or the Bw horizons appeared to be quite different. In the A1 horizon they were identified mainly a hydroxyl-Al (Fe) intergrade smectite (montmorillonite), whereas in the Bw horizon the major component was an intergrade vermiculite originating, at least in part, from chlorite.

**Key Words**—Soil clays, Weathering, Soil vermiculite, Soil smectite, Hydroxy-Al intergrades, Chlorite, Dystrochrept.

### INTRODUCTION

As phyllosilicates are common constituents of soil parent materials, clays from soils of the temperate zone are classically thought to originate from these preexisting phyllosilicates through physical fragmentation and simple transformation (Pédro, 1983). A series of intermediate products may form, the size and composition of which may change during the weathering processes.

Easily weatherable, trioctahedral Fe,Mg-phyllosilicates (chlorite, biotite) are expected to be an important source of soil clays, but dioctahedral Al-micas (muscovite) may also be soil clay precursors (Ross *et al.*, 1982). Transformation of micas to expandable 2:1 minerals is well documented (Fanning *et al.*, 1989; Douglas, 1989). The processes involved are release of K, loss of structural Fe, and decrease in layer charge. Weathering of chlorite in acid soils proceeds through a transformation to vermiculite, with a loss of Fe and Mg (Bain, 1977; Ross *et al.*, 1982; Churchman, 1980). The weathering products of chlorite and trioctahedral micas are therefore expected to have a lower Fe content. Hydroxy-interlayered vermiculite and smectite are formed in acid soils by deposition of hydroxy-Al

polymeric components within the interlayers of these expandable phyllosilicates (Jackson, 1963).

Soils, even in the temperate zone, should be considered as a potential environment for neoformation of clay minerals. The identification of the clay phases that would be stable in the physico-chemical conditions of these soils would be very informative.

The aim of this paper was to separate the different clay species from natural mixtures and to differentiate the simple transformation products from neoformed clays. One soil was chosen as a typical example of acid soils developed from a granite saprolite. A typical Humiferous Acid Brown Soil (a Dystrochrept; USDA, 1986) was subjected to particle size fractionation followed by high gradient magnetic separation (HGMS).

Particle size fractionation helps to isolate large, inherited mineral grains from their weathering products that are generally of a smaller size. HGMS concentrates minerals on the basis of their Fe content (Russell *et al.*, 1984; Righi and Jadault, 1988) and thus provides a tool to isolate Fe-rich minerals from aluminous ones (Weed and Bowen, 1990). This approach permitted relatively homogeneous fractions of soil clays to be mineralogically and chemically characterized.

### SOIL MATERIALS

Clays were separated from a typical Humiferous Acid Brown Soil (French classification, CPCS, 1967) or Typic Dystrochrept (Soil Taxonomy, USDA, 1986) of the Plateau de Millevaches, Massif Central, France. The region is hilly and covered by heaths and conifers. The elevations range from 750 to 950 m. Slopes are rather steep but summits are rounded. The climate is cool (8°C mean annual temperature) and humid (1500 mm mean annual precipitation).

The rocky substrate is composed almost exclusively of granite covered by a saprolite mantle, 2–10 m thick. The soil in question formed from this saprolite. Although the age of the saprolite is not precisely known, it may be of Tertiary age. As a consequence of periglacial disturbance of the saprolite during the last glacial period, the present soils are thought to be no older than 15,000 years. Therefore, soil formation in this area was considered to be a distinct process from the saprolite formation. Only the mineralogical changes that took place during soil formation are considered here.

The soil, located on a summit landscape position at elevation 880 m, was selected as a good example of those widely distributed in this region. A previous study (Righi and Borot, 1985) on particle size distribution within the various horizons has demonstrated that the parent material was homogeneous and without any lithologic discontinuity. The soil profile was sampled according to four major horizons, including A1 and A2 (the two most superficial organo-mineral horizons), Bw (with a typical soil structure) and C (the upper part of the saprolite). A short description of the soil profile is given below, together with some important analytical data (Table 1).

0–8 cm: A1, very dark greyish-brown (10YR 3/2) sandy loam, strong, very fine granulate structure, friable, many medium and fine roots, bleached sand grains, few granite gravels, diffuse smooth boundary.

8–15 cm: A2, dark yellowish-brown (10YR 3/4) sandy loam, weak, fine granular structure, friable, common fine roots, few granite gravels, clear smooth boundary.

15–25(35) cm: Bw, dark yellowish-brown (10YR 4/4) sandy loam, weak, subangular blocky structure, friable, few medium roots, granite gravels, diffuse wavy boundary.

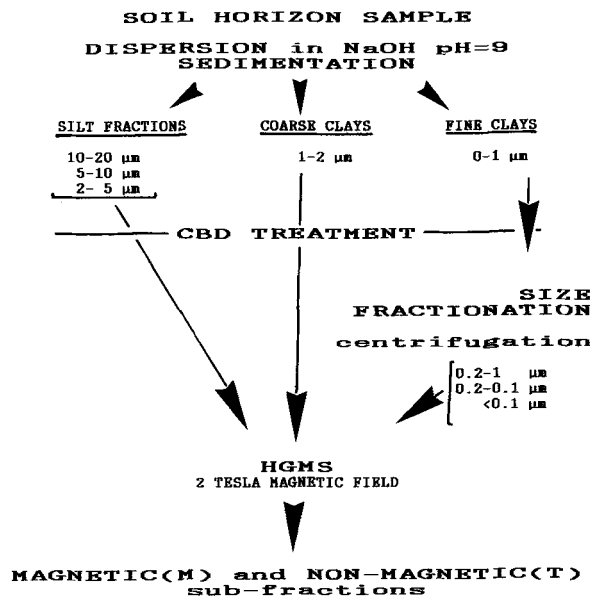

Figure 1. Diagrammatic representation of the successive steps of silt and clay fractionation.

>25(35) cm: C, yellowish-brown (10YR 5/3) sandy loam, weak, subangular blocky structure, friable, gravelly, few roots.

### METHODS

The clay and the silt fractions were obtained by sedimentation after treatment of the organic matter with diluted, Na-acetate buffered H<sub>2</sub>O<sub>2</sub> (pH = 5) and dispersion in a sodic medium (NaOH) at pH 9. The separated fractions (0–1, 1–2, 2–5, 5–10 and 10–20 μm) were then treated with citrate-bicarbonate-dithionite (CBD) (Mehra and Jackson, 1960) to remove crystalline and amorphous iron oxides and oxyhydroxides. Those iron oxides associated with the phyllosilicate surfaces could affect the magnetic separation. However, CBD treatment may induce a slight alteration of some of the Fe-bearing silicates (Douglas, 1967) and partial dissolution of smectites (Stucki *et al.*, 1984).

The 0–1 μm deferrated clay fraction was further divided into <0.1, 0.1–0.2 and 0.2–1 μm fractions by centrifugation using a Beckman J2-21 centrifuge equipped with the JCF-Z continuous flow rotor.

Each of the clay and silt fractions was then subjected to high gradient magnetic separation (HGMS) according to Righi and Jadault (1988). A magnetic fraction (M), retained on the magnetic filter in a magnetic field of 2 T, and a tail fraction (T) were collected. Figure 1 illustrates the successive steps of the fractionation procedure.

X-ray diffraction (XRD) diagrams were obtained from oriented specimens using a Philips diffractometer and Fe-filtered CoK $\alpha$  radiation. For the silt fractions a classical chart recorder was used. The clay fraction

Figure 2. Amounts of the 1–2  $\mu\text{m}$ , 0.2–1  $\mu\text{m}$  and <0.2  $\mu\text{m}$  clay fractions in the different soil horizons, percent of 105°C dry soil. (—): 1–2  $\mu\text{m}$  fraction; (-·-): 0.2–2  $\mu\text{m}$  fraction; (- - -): 0–2  $\mu\text{m}$  (total clay) fraction.

diffractograms were also recorded numerically by a DACO-MP recorder connected to a microcomputer using the Diffrac program of SOCAIM. These diagrams were resolved into their elementary constitutive curves using a least-squares computer program (Lanson and Champion, 1991) that allowed improved measurement of the widths and relative intensities of the diffraction peaks. Pretreatments of the samples included Mg saturation, ethylene glycol solvation, and K saturation followed by heating to 110, 300 and 550°C.

Total analyses were performed on CBD-treated samples according to Jeanroy (1972). Si, Al, Fe, Ti, Mg, Ca, Na and K were analyzed by atomic absorption spectroscopy (AAS).

Cation exchange capacity (CEC) was obtained by saturation with Mg, the excess of Mg salt ( $\text{MgCl}_2$ ) being carefully washed with ethanol. Mg was then exchanged by  $\text{NH}_4$  and analyzed in the exchange solution by AAS.

An acid dissolution treatment (1 N HCl; 80°C overnight) according to DeConinck *et al.* (1975) was used to dissolve chloritic materials, and possibly other trioctahedral minerals (MacEwan and Wilson, 1980). Dissolved Al, Fe, Mg and K were analyzed by AAS.

CEC and HCl dissolution treatments were also performed on CBD-treated samples.

A  $\text{M}^+4\text{Si-R}^{2+}$  ternary system (Meunier and Velde, 1989) was used to represent graphically the chemical composition of the silt and the clay fractions. An average structural formula was calculated for each fraction on a  $\text{O}_{10}(\text{OH})_2$  basis.  $\text{M}^+$  was taken as the sum of the nonexchangeable K content plus the number of charges deduced from the measured CEC. Coordinates for reference low- and high-charge montmorillonite and beidellite were taken from Meunier and Velde (1989). Such a system permitted the separation of phyllosili-

cates according to their layer charge ( $\text{M}^+$  pole), the Si content of the tetrahedral sheet (4Si pole), and the divalent cations in the octahedral sheet ( $\text{Mg}^{2+}$  in the present study).

## RESULTS

The amount of clay in the samples and the proportions of the <0.2, 0.2–1 and 1–2  $\mu\text{m}$  fractions are shown in Figure 2. Total clay (0–2  $\mu\text{m}$ ) increased from 50 g/kg in the C horizon to 120 g/kg in the A1 horizon. Only the fine fractions (<0.2 and 0.2–1  $\mu\text{m}$ ) were increased by soil formation relative to the C horizon.

The CBD-extracted Fe and Al, expressed as  $\text{Fe}_2\text{O}_3$  and  $\text{Al}_2\text{O}_3$ , are given in Table 2. These amounts decreased with an increase in particle size, but was about the same from one horizon to another. An exception is the C horizon where  $\text{Fe}_2\text{O}_3$  was lower and  $\text{Al}_2\text{O}_3$  higher.

Ratios for the magnetic (M) to nonmagnetic (T) fractions are given on a semi-quantitative basis in Table 3. The most important feature is that the M-fractions decreased in the most superficial horizon (A1). In other words, from the C to the A1 horizon, the tendency was to concentrate a more abundant <0.1  $\mu\text{m}$  T-fraction, while the <0.1  $\mu\text{m}$  M-fraction was strongly reduced.

### Mineralogy of the silt fractions

M- and T-fractions from the silt samples exhibit clearly different XRD diagrams (Figure 3). In the T-fractions, the most intense reflections are those of mica (0.989, 0.498 and 0.333 nm), quartz (0.424, 0.333 nm), and feldspar (0.321 and 0.319 nm). Only traces of quartz and feldspar were detected in the M-fractions,

Figure 8. Resolved XRD diagrams from the A1 and Bw horizon,  $<0.1 \mu\text{m}$  T-fraction after Na-citrate treatment. A1 horizon sample: a—Mg saturated and ethylene glycol solvated, curves as in Figure 5; b—Li saturated, heated and ethylene glycol solvated (Greene-Kelly test), experimental curve. Bw horizon sample: Mg saturated and ethylene glycol solvated, curves as in Figure 5.  $\text{CoK}\alpha$  radiation, d-spacings in nm.

on the A1,  $<0.1 \mu\text{m}$  T-fraction. The result clearly indicated that the smectite layers were essentially montmorillonitic (Figure 8).

The composition of the Na-citrate extract was also different according to the sample from which it was obtained. From the C horizon,  $0.2\text{--}1 \mu\text{m}$ , and Bw horizon,  $<0.1 \mu\text{m}$  T-fractions, large amounts of MgO (37 and 30% of total MgO, respectively) were extracted with  $\text{Al}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3$  (Table 4). Conversely, only small amounts of MgO were extracted from the A1 fractions.  $\text{Al}_2\text{O}_3$  and  $\text{Fe}_2\text{O}_3$  were largely extracted from the A1,  $<0.1 \mu\text{m}$  T-sample, and to a lesser extent from A1,  $0.2\text{--}1$  and  $1\text{--}2 \mu\text{m}$  M-fractions.

#### Cation exchange capacity

CEC varied from  $0.085 \text{ eq/kg}$  (C,  $10\text{--}20 \mu\text{m}$  M-fraction) to  $0.344 \text{ eq/kg}$  (Bw,  $<0.1 \mu\text{m}$  T-fraction), and increased from the larger to the finer fractions (Figure 9). Within the fine clay samples ( $<1 \mu\text{m}$ ) the CEC was the lowest for those from the A1 horizon. The highest CEC was observed in the Bw horizon fine clays ( $<0.1 \mu\text{m}$ ).

#### Total chemical analysis

The results from the chemical analyses are given in Table 5, and the relative amounts in Al, Fe and Mg atoms are plotted in a triangular coordinate diagram with the three poles attributed to 100% Al, 50% Fe, and 50% Mg, respectively. Except for the three finest fractions from the A1 horizon, all the representative plots fell onto a line tied to the 100%—Al pole (Figure 10). This indicates that the Fe/Mg atomic ratio is equal for all these samples. Moreover, the relative Al content

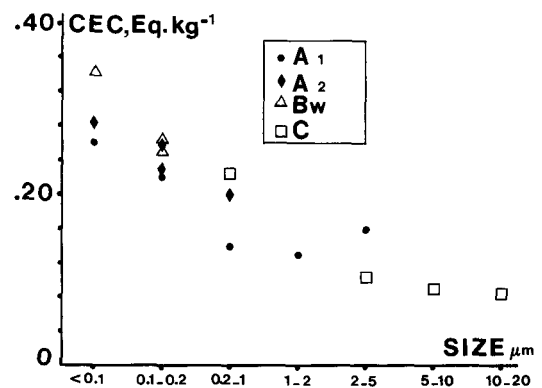

Figure 9. CEC values for the silt and clay fractions.

increases from the silt fractions in the C horizon to the finest clay fractions in the Bw and A2 horizons. The plots for the three finest fractions from the A1 horizon are shifted toward a higher Fe/Mg ratio line.

The Si/Al ratios (Figure 11) fall between 1.6 and 1.8 for the silt and coarse clay fractions ( $1\text{--}2 \mu\text{m}$ ), but are lower ( $1.2\text{--}1.4$ ) for the fine clay fractions. The lowest values (0.8, 0.9 and 1.1) were observed in the finest fractions from the A1 horizon.

The CEC values and the Si/Al ratios (except for those of the A1 horizon) are strongly correlated with the  $\text{K}_2\text{O}$  content. The regressions are:  $\text{CEC eq/kg} = -9.26 \text{ K}_2\text{O}\% + 0.56$ ;  $r = -0.94$  (Figure 12) and  $\text{Si/Al} = 0.21 \text{ K}_2\text{O}\% + 0.63$ ;  $r = 0.91$  (the A1 horizon fine fractions are excluded) (Figure 13).

#### HCl dissolution

1 N HCl dissolution treatment was done on the  $<0.1 \mu\text{m}$  T-fractions from the Bw and A1 horizons.  $\text{Fe}_2\text{O}_3$  was completely extracted from the two samples, but only 59% of the total  $\text{Al}_2\text{O}_3$  was removed (Table 6). The contents of  $\text{K}_2\text{O}$  and MgO extracted by the treatment were strongly different according to the sample. 92% of MgO and 90% of  $\text{K}_2\text{O}$  were extracted from the Bw horizon sample, but only 47% and 49%, respectively, from the A1 horizon.

## DISCUSSION

The silt and clay fractions from the C horizon contain chlorite layers that could not be separated by HGMS from the mica, vermiculite, and interstratified mica/vermiculite layers. This suggests that all these layers were closely associated in the same silt or clay particles. If ferruginous chlorite layers had been present as discrete particles, they should have been easily separated by HGMS (Ghabru *et al.*, 1990; Weed and Bowen, 1990; Righi and Jadault, 1988).

Compared to that of the C horizon, the proportion of chlorite layers is strongly reduced in the fine silt fraction ( $2\text{--}5 \mu\text{m}$ ) of the A1 horizon. Moreover, chlorite

Figure 10. Relative contents in Al, Fe and Mg atoms in the separated fractions. 1: 10–20  $\mu\text{m}$ ; 2: 5–10  $\mu\text{m}$ ; 3: 2–5  $\mu\text{m}$ ; 4: 1–2  $\mu\text{m}$ ; 5: 0.2–1  $\mu\text{m}$ ; 6: 0.1–0.2  $\mu\text{m}$ ; 7: <0.1  $\mu\text{m}$ .

had totally disappeared from the coarse clay of that horizon (1–2  $\mu\text{m}$ ), but was found in the finer clay fraction (<1  $\mu\text{m}$ ). The same is true for the interstratified mica/vermiculite and vermiculite layers. These were present in the fine silt fractions but have disappeared from the A1 horizon coarse clays.

The distribution of mica layers in the different fractions was quite the opposite. Mica layers are the major component of the A1, 1–2  $\mu\text{m}$  fractions, and their proportion progressively decreases with fraction size. Thus, it may be concluded that during fragmentation and/or simple transformation of the large phyllosilicates, clusters of chlorite, mica/vermiculite and vermiculite were

Figure 11. Si/Al atomic ratio for the separated fractions.

preferentially affected. In good agreement is the decrease of the 0.153 and 0.154 nm XRD reflection intensities (trioctahedral minerals) and the increase of the 0.150 nm reflection (dioctahedral minerals) from the largest to the smallest particles. Ross (1975) and Vicente *et al.* (1977) have described changes during weathering from trioctahedral to dioctahedral structure. The peak at 0.153 nm could be attributed to an intermediate dioctahedral-trioctahedral structure and/or a strongly oxidized biotite (Fordham, 1990).

The relative decrease in the Mg and Fe atom contents could also be explained by preferential weathering of Fe, Mg-rich minerals (chlorite, trioctahedral vermiculite) from the coarse fractions. This resulted in the concentration of more resistant mica layers in the coarse clay fractions as the chlorite, mica/vermiculite and vermiculite residues were accumulated in the finer clays.

Figure 12. CEC vs nonexchangeable  $K_2O$  for the separated fractions. Symbols and figures as in Figure 10.

Fe derived from the weathered minerals appears to accumulate in the finest fractions as amorphous and/or crystalline iron oxides. As these compounds were extracted by the CBD treatment, it was not possible to specify the type of iron oxides present. However, in acid brown soils developed from crystalline rocks, amorphous iron oxides generally account for the great part of the CBD-extractable Fe (Jeanroy *et al.*, 1984). The rather large amounts of material extracted by the CBD treatment indicate that, in addition to the transformation of phyllosilicates, dissolution was also an important weathering process in this soil.

If one makes the assumption that the finest fractions were also the most weathered, the changes from the 0.2–1 to the  $<0.1 \mu\text{m}$  T-fractions indicate that weathering proceeds through the transformation of mica layers to mica/vermiculite and vermiculite layers. Smectite layers were finally formed in the finest fraction. These minerals are dioctahedral. Smectite, vermiculite and interlayered mica/vermiculite were commonly described as weathering products of chlorite and/or mica in acid soils (Gjems, 1967; DeConinck and Herbillon, 1969; Bain, 1977; Ross *et al.*, 1982; Douglas, 1989).

A good agreement was found between the mineralogy of the various fractions, their  $K_2O$  content, and the CEC values. XRD showed a decrease of the proportion of mica layers from the larger to the finer fractions, while the proportions of interstratified vermiculite or smectite layers increased. This is consistent with a decrease in the  $K_2O$  content and an increase in the CEC.

Contrary to what might be expected, the  $K_2O$  content is higher in the A1,  $<0.1 \mu\text{m}$  T-fraction than in the equivalent Bw horizon sample that contained more mica layers. This might be explained if the A1 horizon mica layers did not occur as discrete particles, but were interstratified with the smectite and vermiculite layers.

The decrease of both the Si/Al atomic ratio and the  $K_2O$  content corroborates the relative accumulation of

Figure 13. Si/Al atomic ratio vs nonexchangeable  $K_2O$  for the separated fractions. A1, 0.2–1, 0.1–0.2 and  $<0.1 \mu\text{m}$  samples are excluded from the correlation curve. Symbols and figures as in Figure 10.

aluminum-rich minerals in the weathering products. Large proportions of kaolinite or gibbsite were not expected in the finest fractions, and XRD did not show increasing amounts of these minerals with a decrease in particle size. Moreover, increasing amounts of kaolinite and gibbsite would simultaneously lower both the CEC value and the  $K_2O$  content, and exactly the reverse was observed.

The composition of the three finest fractions from the A1 horizon showed higher Fe/Mg ratios than the others, suggesting that either the source minerals for these fine clays, or the weathering process were different. A clearly distinct behavior of these fractions was also observed on the Si/Al– $K_2O$  diagram. For a given  $K_2O$  value the Si/Al ratios are lower than in the other samples. This indicates that the source minerals for the A1 horizon fine clays were not the same as for those of the Bw or A2 horizons. The lower Si/Al ratio could be explained by a higher proportion of weathered dioctahedral aluminous micas in these fractions. An increased hydroxy-Al interlayering could also be a reason for the decrease of the Si/Al ratio. However, subtraction of Al extracted by the Na-citrate treatment, and which was assumed to be interlayered hydroxy Al, did not significantly alter the Si/Al ratio. Moreover, an extended hydroxy-Al interlayering should have strongly reduced the CEC (Barnhisel and Bertsch, 1989). Such minerals should have a low CEC and a low  $K_2O$  content. As a consequence they would have diverged from the CEC– $K_2O$  relationships.

HCl treatment has been used to dissolve chlorite and other weathered trioctahedral minerals (DeConinck *et al.*, 1975; Bain, 1977; Ross *et al.*, 1982). Adams and Kassim (1983) demonstrated that a 1 N HCl treatment virtually removed vermiculite produced from chlorite but had less effect on vermiculite produced from illite. Thus, the fact that about 90% of MgO (or  $K_2O$ ) was extracted from the Bw,  $<0.1 \mu\text{m}$  T-fraction by the HCl treatment is indicative of a large proportion of chlorite and trioctahedral weathering products in this sample.

Table 6. Composition of 1 N HCl extracts from A1 and Bw clay fractions.

Sample	Al <sub>2</sub> O <sub>3</sub>		Fe <sub>2</sub> O <sub>3</sub>		MgO		K <sub>2</sub> O	
	(1)	(2)	(1)	(2)	(1)	(2)	(1)	(2)
A1 <0.1 μm T	167	59	71	92	7.5	47	17.7	49
Bw <0.1 μm T	175	59	69	100	23.0	92	19.1	90

(1) g/kg, 105°C, dry sample; (2) percent total oxide.

Conversely, only about 50% of MgO (or K<sub>2</sub>O) was extracted from the equivalent fraction from the A1 horizon. This suggests a higher chemical stability, attributed to a greater proportion of weathered dioctahedral phyllosilicates, for the A1 horizon fine clays.

Differences in the XRD behavior of the finest non-magnetic fractions (<0.1 μm T-fraction) from either the Bw or the A1 horizons were also observed after Na-citrate treatment. Before treatment, the samples were typical of an intergrade vermiculite mineral (no expansion with ethylene glycol, incomplete collapse when K-saturated and heated). Following the Na-citrate treatment, the A1 horizon fraction exhibited an increased proportion of smectite layers and further collapse following K-saturation and heating. This is an indication that most of the interlayered material was extracted by the treatment. As the extract contains mainly Al and Fe, the hydroxy-Al and Fe interlayers are presumed to have been extracted. Although hydroxy-Fe compounds have been suggested (Singleton and Harward, 1971; Vicente-Hernandez *et al.*, 1983; Ghabru *et al.*, 1990), it is always possible that the Fe extracted by the Na-citrate treatment included some Fe-oxides incompletely removed by the previous CBD treatment, or Fe from the 2:1 layers themselves. The same would be true for a portion of the extracted Al.

Despite the fact that Fe and Al were extracted from the Bw horizon fraction at the same levels as from the A1 horizon fraction, only slight changes were observed in the XRD behavior of the treated Bw sample. A large part of the interlayered compounds was apparently not extracted. This could be the result of a more stable, better-organized hydroxy-Al (Fe) interlayered sheet. Such a hydroxy-Al (Fe) interlayered mineral should have a lower CEC than that of minerals in which interlayering is less pronounced (Barnhisel and Bertsch, 1989). This was not observed in the present instance. The CEC of the Bw-horizon fraction is greater than that of the A1 horizon. Thus, a more highly developed hydroxy-Al (Fe) interlayered sheet is not a satisfying explanation for the Bw horizon sample data.

Compared to the A1 fraction, far larger amounts of Mg were extracted from the Bw fraction by the Na-citrate treatment. This could be the result of partial dissolution of chlorite layers (Figure 7). Partial dissolution of chlorite with Na-citrate has been demonstrated by Ghabru *et al.* (1990). The poorly crystalline parts

of the minerals were dissolved by the treatment which, however, did not result in the complete conversion of a true chlorite to vermiculite. Therefore, it is likely that a chlorite mineral with a more or less stable interlayer is a component of the Bw horizon fine clay fraction. As the Na-citrate treatment does not selectively dissolve the interlayered hydroxide sheet, the remaining undissolved minerals may contribute to the XRD intergrade behavior still observed for the treated sample.

The characteristics and origin of the finest nonmagnetic (T) fractions from either the A1 or the Bw horizons appear to be quite different. In the A1 horizon this fraction was identified mainly as a hydroxy-Al (Fe) intergrade smectite that may derived from the weathering of mica layers. In the Bw horizon the major component was an intergrade vermiculite originating, at least in part, from chlorite layers. These differences are likely to be linked to the A1 horizon being more acid and richer in organic matter than the Bw horizon. According to Schwertmann (1976), mafic chlorite is completely dissolved in strongly acid, organic soils, whereas it transforms to vermiculite in weakly acid, poorly organic soils.

The chemical analyses were plotted in the M<sup>+</sup>-4Si-R<sup>2+</sup> ternary system (Figure 14) but, as XRD showed that both coarse and fine fractions are composed of more than one phyllosilicate species, the chemical analysis represents the bulk composition of a mixture. This means that the linear trends depicted in Figure 14 must be interpreted as a two-component mixture. The extrapolation of a line was assumed to give the composition of one of the two pure components.

In Figure 14 the chemical analyses of the silt and coarse-clay fractions are distributed along a line joining the R<sup>2+</sup>-pole on one side, and the composition of a high-charge beidellite on the other side. However, the high-charge beidellite pole is not reached and, moreover, beidellite was not identified by XRD in the coarse clays. Interpretation of Figure 14 corroborates the idea of preferential dissolution of vermiculite and chlorite layers, leaving a residue consisting of K-depleted, charge-reduced mica layers with Al in the octahedral sheet.

The chemical compositions of the fine clay fractions from the Bw and A2 horizons were clearly off of the coarse fraction line, indicating a change in weathering pathway. A decrease in layer charge and increase in Si-

Figure 14. Chemical composition of the separated fractions in the  $M^+$ -4Si- $R^{2+}$  ternary system. Mu: muscovite, Mo: montmorillonite, Be: beidellite, h: high charge, l: low charge. Symbols and figures as in Figure 10. Compositions of muscovite, beidellite and montmorillonite are from Meunier and Velde (1989).

atom content are involved. Although there is no direct evidence, such changes may indicate neoformation processes.

The chemical compositions are distributed along several lines joining montmorillonite in the  $M^+$ -4Si- $R^{2+}$  diagram. Each transformed coarse mineral seemed to produce a montmorillonite. The weathering end products in the Bw and A2 horizons were not beidellite, as has been reported in other studies (Wilson, 1987). Buurman *et al.* (1976) have shown that smectites that had formed from chlorite in alpine soils were montmorillonite.

The composition of the fine clays from the A1 horizon are different from the others. They are on a line joining muscovite and high-charge montmorillonite. This represents a greater contribution of weathered dioctahedral micas in these fractions.

### CONCLUSION

Size fractionation associated with HGMS has provided relatively homogeneous fractions of soil clays, greatly enhanced mineral characterization, and clarified possible weathering pathways. Weathering of large phyllosilicates preexisting in the saprolite involves physical fragmentation and mineralogical transfor-

mations. These processes vary according to the composition of the minerals and the physico-chemical characteristics of the soil horizons.

Chlorite and vermiculite are more strongly affected by physical fragmentation than the mica layers, contributing to the formation of the fine clays as mica residues accumulated in the coarse clay fractions. The most abundant end products of the weathering processes are hydroxy-Al(Fe) intergrade dioctahedral smectites in the A1 horizon and intergrade dioctahedral vermiculites in the less acid, less organic-rich Bw horizon. The intergrade character of vermiculite is related partly to hydroxy-Mg compounds.

The physical fragmentation of large particles is strongly related to chemical weathering. This process involves simultaneous loss of Fe and Mg from the mineral structure, leaving more aluminous dioctahedral minerals. Dissolution of the preexisting minerals leads to the precipitation of amorphous and/or crystalline Fe- and Al-oxides that are also important in the finest clays. Neoformation of phyllosilicate layers may not be excluded. The stable clay phase in this temperate, acid soil appears to be a montmorillonite, the layer charge of which appears to be controlled by the composition of the precursor minerals.
