

AA DOR — AN ECLIPSING SUBDWARF – BROWN DWARF BINARY

T. Rauch^{1,2}

AA DOR is an eclipsing, close, post common-envelope binary (PCEB) consisting of a sdOB primary star and an unseen secondary with an extraordinary small mass ($M_2 \approx 0.066M_\odot$) – formally a brown dwarf (see Rauch 2004 for details). In a spectral analysis of AA DOR, Rauch (2000) determined $T_{\text{eff}} = 42 \text{ kK}$ and $\log g = 5.2$ (cgs). The determination of the components' masses by comparison of these results with evolutionary models of Driebe et al. (1998) shows a discrepancy to masses derived from radial-velocity and the eclipse curves (Hilditch et al. 2003) – $\log g = 5.5$ would be necessary in order to achieve an intersection at $M_1 \approx 0.330M_\odot$.

Possible reasons for this discrepancy may be too optimistic error ranges in Rauch (2000) or in the analysis of light curve and radial-velocity curve, or that the evolutionary models of Driebe et al. (1998) are not appropriate in the case of AA DOR since these are post-RGB models for non-CE stars.

Since the decrement of the hydrogen Balmer series is a sensitive indicator for $\log g$, 107 high-resolution échelle spectra with short exposure times (180 sec) have been taken in Jan 2001 with UVES attached to the ESO VLT. Additional medium-resolution longslit spectra have been taken at the 2.3m telescope at SSO in Sept 2003 with the DBS. However, the analysis of both, the UVES spectra (Rauch & Werner 2003) and the DBS spectra, shows that a $\log g$ higher than 5.2 results in a worse fit to the observation.

Since the secondary is heated by irradiation of the primary up to $\approx 20 \text{ kK}$, one can expect a weak $H\beta$ emission in the UVES spectra. However, we do not find any signature of the secondary. The emission in the line core of $H\beta$ (Fig. 1) comes clearly from the primary, its phase dependence is likely due to an irradiation effect of the heated secondary on the primary which increases its T_{eff} by $\approx 7 \text{ kK}$, i.e. the primary – taken as an isolated star – would have only $T_{\text{eff}} \approx 35 \text{ kK}$, resulting in a $\approx 10\%$ smaller mass. A phase-dependent spectral analysis is presently per-

formed in order to investigate on this effect. It appears possible that this is one of the main reasons for the disagreement in the mass-radius relation.
