Abstract

Malaria is endemic in Guinea; however, the extent and role in transmission of asymptomatic malaria are not well understood. In May 2023, we conducted a rapid community survey to determine *Plasmodium falciparum* (*P. falciparum*) prevalence among asymptomatic individuals in Middle Guinea (Prefecture Dalaba) and Forest Guinea (Prefecture Gu ck dou). In Dalaba, 6 of 239 (2.1%, confidence interval (CI) 0.9–4.8%) individuals tested positive for *P. falciparum* by a rapid diagnostic test (RDT), while in Gu ck dou, 147 of 235 (60.9%, CI 54.5–66.9%) participants tested positive. Asymptomatic malaria needs to be considered more strongly as a driver of transmission when designing control strategies, especially in Forest Guinea and potentially other hyper-endemic settings.

Key results

- The prevalence of asymptomatic malaria was very high (60.9%, CI 54.5–66.9%) in the selected communities in Forest Guinea.
- The prevalence was expectedly low (2.1%, CI 0.9–4.8%) in the selected communities in Middle Guinea.
- Current control strategies in Forest Guinea seem insufficient to reduce malaria prevalence and, likely, transmission.
- Both policies and control strategies need to more proactively consider asymptomatic malaria in hyper-endemic settings.

Summary

Malaria is endemic in Guinea; however, the extent and role in transmission of asymptomatic malaria are not well understood. In May 2023, we conducted a rapid community survey to determine *Plasmodium falciparum* (*P. falciparum*) prevalence among asymptomatic individuals in Middle Guinea (Dalaba) and Forest Guinea (Gu ck dou). We used a cluster sampling approach with the purposive selection of two prefectures and four communities and the full enrolment of all individuals in the selected communities. The prevalence was calculated with a 95% confidence interval (CI). In Dalaba, 6 of 239 (2.1%, CI 0.9–4.8%) individuals tested positive for *P. falciparum* by a rapid diagnostic test (RDT), while in Gu ck dou, 147 of 235 (60.9%, CI 54.5–66.9%) participants tested positive. Asymptomatic malaria needs to be considered more strongly as a driver of transmission when designing control strategies, especially in Forest Guinea and potentially other hyper-endemic settings.

Introduction

Despite decades of control efforts, malaria remains endemic in many countries in Africa and is a major cause of morbidity and mortality, particularly in children [1]. The World Health Organization’s current guidelines focus on ‘test, treat, and track’ strategies for symptomatic individuals, complemented by preventive efforts such as vector control and chemoprophylaxis for high-risk groups [2, 3]. However, there is growing recognition that many individuals infected with malaria may not display overt symptoms, due to immune protection from previous exposures and other factors, but they may still contribute to overall disease transmission [4–6]. The extent to which

Demographics of study population in Guekedou and Dalaba

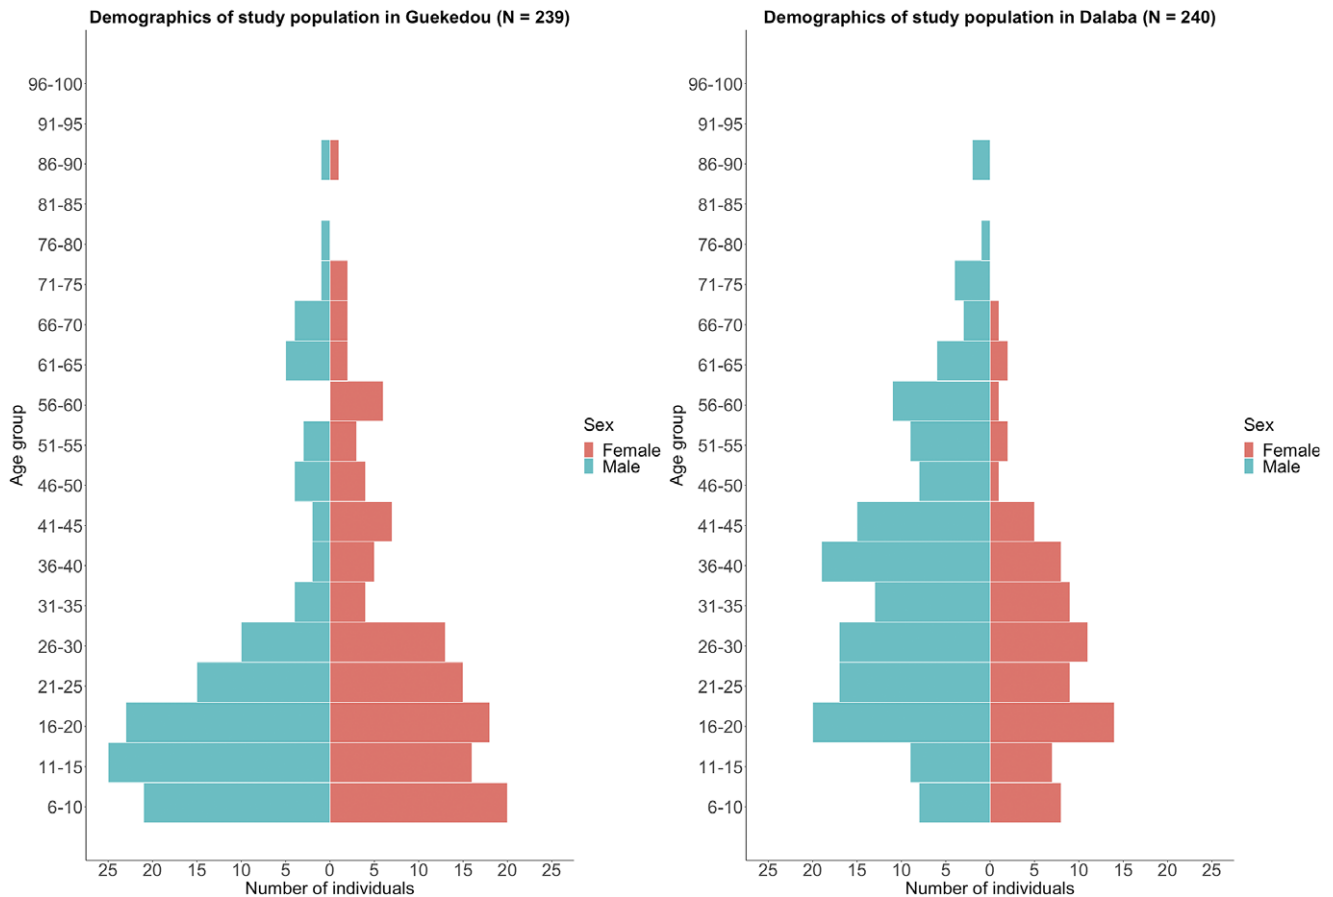

Figure 1. Demographic characteristics of study participants by prefecture. Participants aged below 6 were not eligible for inclusion.

these asymptomatic infections exist in a population may help to determine the effectiveness of existing control efforts. Guinea is highly endemic for malaria, with Forest Guinea being a hyper-endemic area, experiencing year-round transmission [7, 8], while the holoendemic coastal and middle regions of the country see more seasonal transmission [8–10]. Overall malaria incidence ranged from 87 to 101 per 1,000 per year between 2006 and 2010 [9]. Regional differences in the incidence of non-severe malaria ranged from 57 to 103 per 1,000 per year in 2011 [11]. In 2021, malaria prevalence among symptomatic and asymptomatic children aged 6–59 months ranged from 1.5% (Conakry capital region) to 55.0% (N’Zérékoré, Forest Guinea) [12], and in 2011, parasite prevalence in all age groups ranged from 3% (Conakry capital region) to 66% (Forest Guinea). [11] As these surveys were conducted, additional control efforts have been implemented in hyper- and holoendemic settings, notably the roll-out of seasonal chemoprophylaxis to high-risk groups. The main parasite present in Guinea is *Plasmodium falciparum* (*P. falciparum*) [8].

Given the relative lack of recent data regarding the current prevalence of asymptomatic malaria in individuals over the age of 5 and subsequently the potential contribution to transmission, we sought to estimate the prevalence of asymptomatic malaria in older children and adults in Middle Guinea and Forest Guinea.

Methods and materials

As part of a prospective, longitudinal study on acute febrile illness (AFI) in two prefectures in Guinea, we conducted a rapid community survey in May–June 2023, which is the beginning of the rainy season. Our two study areas were Dalaba, in Middle Guinea, and Guéckédou, in Forest Guinea. We used a three-level cluster sampling approach. The two prefectures were chosen purposively as representing the diversity of prevalence and incidence of AFI in Guinea based on past surveillance data. Within each prefecture, two communities were chosen purposively based on guidance from the local health authorities and experts for their suitability, which included consideration of accessibility and research fatigue on the part of the communities. All individuals within these communities were eligible to be enrolled in the study if they were 6 years old or older, did not currently show any clinical signs of AFI, and were able and willing to provide consent either themselves or via their parents or guardians for a socio-demographic and behavioural questionnaire and finger-prick blood sample for a malaria rapid diagnostic test (RDT) to detect *P. falciparum* using the Bioline™ Malaria Ag P.f Test Kit from Abbott. The prevalence was calculated with a 95% confidence interval (CI). The data were analysed in R using RStudio.

Table 1. Prevalence of asymptomatic malaria in the prefectures Dalaba and Guéckédou in May or June 2023 by age group

Age	Prevalence of Dalaba (95% CI)	Prevalence of Gueckedou (95% CI)
All	2.09 (0.90–4.80)	60.85 (54.48–66.87)
6–10	6.25 (0.32–28.33)	82.50 (68.05–91.25)
11–15	12.50 (3.50–63.02)	87.50 (73.89–94.54)
16–20	0.00 (0.00–10.15)	75.61 (60.66–86.17)
21–25	3.85 (0.20–18.89)	46.67 (30.23–63.86)
26–30	3.57 (0.18–17.71)	45.45 (26.92–63.34)
31–35	0.00 (0.00–14.87)	37.50 (13.68–69.43)
36–40	0.00 (0.00–12.46)	42.86 (15.82–74.95)
41–45	0.00 (0.00–16.11)	62.5 (30.57–86.32)
46–50	0.00 (0.00–29.91)	50.00 (21.52–78.48)
51–55	0.00 (0.00–25.88)	16.67 (0.85–56.35)
56–60	0.00 (0.00–25.88)	16.67 (0.85–56.35)
61–65	0.00 (0.00–32.44)	0.00 (0.00–35.43)
66–70	0.00 (0.00–48.99)	16.67 (0.85–56.35)
71–75	0.00 (0.00–48.99)	0.00 (0.00–56.15)
76–80	0.00 (0.00–94.87)	100.00 (5.13–100.00)
81–85	NaN	NaN
86–90	0.00 (0.00–65.76)	50.00 (2.56–97.44)
>90	NaN	NaN

Results

In Guéckédou, 239 individuals met the inclusion criteria, and in Dalaba, 240. All of them were included in the study, with RDT results being available for 474 across both sites. In Guéckédou, 51% of participants were male, and in Dalaba, 68% of participants were male. The median age in Guéckédou was 20 years (standard deviation (SD) 18.54), and in Dalaba, it was 30.5 years (SD 17.37). [Figure 1](#) gives an overview of the age and sex breakdown at both study sites. In Dalaba, 6 of 239 (2.1%, CI 0.9–4.8%) individuals tested positive for *P. falciparum* by RDT, while in Guéckédou, 147 of 235 (60.9%, CI 54.5–66.9%) participants tested positive. Positivity decreased with increasing age in both prefectures (see [Table 1](#)), with children being most affected.

Discussion and conclusion

Forest Guinea is a hyper-endemic area for malaria; despite this, the results were still higher than expected given that only asymptomatic individuals were eligible to participate. Results would not have been expected to be as low as in Dalaba, which is not in a hyper-endemic zone, and our sample had a higher median age. However, the difference is large enough to not be fully explained by these two factors alone.

The more expected results from Dalaba using the same RDT and eligibility criteria should reduce the likelihood of the results in Guéckédou having been influenced by quality issues with the

RDT. The results from the second study can therefore be seen as a control for the validity of the test kits. The study is potentially biased by the purposive sampling applied when selecting the communities as one of the criteria applied was the possibility for the study team to access the field site, meaning those communities with better road access were more likely to be chosen. Additionally, we only conducted malaria RDTs and not microscopy in this study. For confirmation and further investigation of the results, follow-up with microscopy would be recommended, especially to ascertain the risk of transmission through observation of gametocytes.

As Forest Guinea experiences year-round transmission, we expect these results to not be a singular phenomenon; however, we strongly suggest a repeat sampling during or at the end of the rainy season. Dalaba experiences seasonal transmission patterns, with peak incidence between July and October and the beginning of the rainy season seeing lower malaria prevalence [8]. We expect the prevalence of asymptomatic malaria to be significantly higher during or at the end of the rainy season in Dalaba.

While additional research is needed to explore these results further, they suggest that current control strategies in Forest Guinea are likely insufficient with respect to malaria transmission, putting children and other vulnerable groups at risk of severe disease. National decision-makers should consider the role of asymptomatic malaria as a driver of transmission in developing policies and intervention strategies in the future. The results also highlight the limitations of test-to-treat approaches for symptomatic individuals as a disease control strategy as they exclude a significant group of individuals. Further approaches to target and limit transmission in asymptomatic groups may be warranted, in addition to other standard control measures such as vector control and (seasonal) chemoprophylaxis for high-risk groups.

Additionally, we recommend that data collection and analysis for malaria control should also consider older children and adults. Currently, the focus is primarily on children below the age of 6. While this is an important risk group for morbidity management, from the point of transmission including other age groups would also be valuable and help to determine prevalence profiles in other vulnerable groups, such as pregnant women. Ideally, such data should be not only collected regularly but also made publicly available for analysis, within the bounds of privacy considerations.

Data availability statement. Due to the very small number of respondents in some age and gender (other) categories, the data cannot be made publicly available as they are potentially identifying.
